ABSTRACT

Introduction  Sleep length has been associated with obesity and various adverse health outcomes. The possible association of sleep length and respiratory symptoms has not been previously described. The aim of this study was to investigate the association between sleep length and respiratory symptoms and whether such an association existed independent of obesity.

Methods  This is a multicentre, cross-sectional, population-based study performed in 23 centres in 10 different countries. Participants (n=5079, 52.3% males) were adults in the third follow-up of the European Community Respiratory Health Survey III. The mean±SD age was 54.2±7.1 (age range 39–67 years). Information was collected on general and respiratory health and sleep characteristics.

Results  The mean reported nighttime sleep duration was 6.9±1.0 hours. Short sleepers (<6 hours per night) were n=387 (7.6%) and long sleepers (≥9 hours per night) were n=271 (4.3%). Short sleepers were significantly more likely to report all respiratory symptoms (wheezing, waking up with chest tightness, shortness of breath, coughing, phlegm and bronchitis) except asthma after adjusting for age, gender, body mass index (BMI), centre, marital status, exercise and smoking. Excluding BMI from the model covariates did not affect the results. Short sleep was related to 11 out of 16 respiratory and nasal symptoms among subjects with BMI ≥30 and 9 out of 16 symptoms among subjects with BMI <30. Much fewer symptoms were related to long sleep, both for subjects with BMI <30 and ≥30.

Conclusions  Our results show that short sleep duration is associated with many common respiratory symptoms, and this relationship is independent of obesity.

INTRODUCTION

Over the past several decades, the prevalence of obesity has grown to epidemic proportions.1,2 At the same time, there has been a similar epidemic of chronic sleep deprivation.2–4 Studies have shown that the average sleep duration has decreased 1–2 hours over the last decades.2 According to annual surveys

Key messages

What is the key question? Is sleep length associated with respiratory health and is this relationship independent of obesity?

What is the bottom line? Short sleep duration is associated with many common respiratory symptoms, and this relationship is independent of obesity.

Why read on? Respiratory symptoms have so far not been the main focus in studies on causal pathways of short sleep duration but, given our results, some respiratory symptoms might directly impact sleep quality and increase the risk of short sleep duration.
sleepers are at an increased risk for obesity. In a recent meta-analyses of 16 studies including in total 285,452 adults, both short sleep duration and long sleep duration were associated with an increased risk of weight gain, but only short sleep duration increased the risk of obesity. However, obesity has also been identified as a risk factor for both asthma and chronic bronchitis, as well as obstructive sleep apnoea (OSA). In addition, several respiratory symptoms are related to obesity. 

Despite the reported associations between sleep length and obesity, and obesity and respiratory health, to the best of our knowledge, no published studies have shown whether there is an independent association between sleep duration and respiratory symptoms. Since existing data show associations of both obesity and sleep duration and obesity and respiratory health, it is important to explore the associations of sleep duration and respiratory health and the role of obesity in this context.

The aim of this study was to investigate the possible association between sleep length and respiratory symptoms and whether it is independent of obesity.

**METHODS**

**Subjects**

This is a cross-sectional study, and participants are adults taking part in the third follow-up of the European Community Respiratory Health Survey (ECRHS, www.ecrhshs.org) III, an international, multicentre, population-based study of asthma and allergy, which was first performed in the early 1990s. Detailed descriptions of the methods for ECRHS I and ECRHS II have been published elsewhere. Briefly, participating centres were first randomly selected samples of subjects aged 20–44 years. Participants completed a short postal questionnaire about asthma and asthma-like symptoms (sample 1). Additionally, about 20% random subsamples of responders were invited for a more detailed questionnaire administered by an interviewer (sample 2). Participants in this study belong to sample 2.

Ethical approval for the study from local research ethics committees and written consent from participants were obtained.

**Questionnaires and measurements**

Participants completed the core ECRHS questionnaires on smoking, other lifestyle and environmental factors, general and respiratory health and chronic disorders. ‘Ever asthma’ was defined as reporting ever having had asthma where the diagnosis had been confirmed by a doctor, and ‘Current asthma’ was defined as having at least one asthma-related symptom in the last 12 months. Participants were also asked whether they had a problem with sneezing or a runny or blocked nose without having the influenza in the last 12 months.

Chronic obstructive pulmonary disease (COPD) was considered present if subjects reported physician-diagnosed COPD. Chronic bronchitis was defined as having cough or phlegm for at least 3 months every year for at least two consecutive years. The presence of CVD was determined by a positive response to ever having angina, heart attack, coronary heart disease or stroke. Nocturnal gastro-oesophageal reflux (nGOR) was defined as reporting heartburn or belching when in bed more often than once a week for the last 3 months.

Information on diagnosed depression, hypertension, diabetes and stroke was also collected.

Subjects were asked how often they usually exercised so much that they get out of breath or sweat. Answers ranged from never to every day, and those who answered ≥2 times per week were considered to exercise on a regular basis.

Height and weight was measured by field workers according to a standardised procedure.

**Sleep-related questions**

All participants were asked to fill in a short questionnaire on their sleep (see supplement). Participants answered the question: how much sleep do you estimate that you get on average each night? They were classified as short sleepers (<6 hours/night), normal sleepers (6–9 hours/night) and long sleepers (≥9 hours/night), in accordance with classifications used in most previous studies on health effects of sleep duration.

Participants also answered the Epworth Sleepiness Scale.

**Statistical methods**

Data are presented as number and percentage or mean±one SD, depending on distribution. For bivariate analysis, the χ² test, t-test and one-way analysis of variance were used for nominal and continuous variables. Logistic regression was used for multivariable analyses to estimate the association between sleep length and respiratory symptoms. Given that obesity is strongly related to both sleep length and to respiratory disorders, multivariable models were built both with and without BMI adjustment. We also stratified results according to BMI into two groups: subjects with BMI <30 and BMI ≥30. The logistic regression models for the association between short sleep and respiratory symptoms and disorders were also fitted separately for each country. Results for the association were pooled across countries using random effects meta-analysis. Heterogeneity between the countries in the association between short sleep and respiratory health were analysed. STATA V13.0 was used for all statistical analyses.

**RESULTS**

**The study cohort**

We included a total of 5079 subjects (52.3% males) from 23 centres in 10 countries (Australia, Britain, Denmark, Estonia, France, Germany, Iceland, Norway, Spain and Sweden).
The mean age (±SD) of the cohort was 54.2±7.1 years (range: 39–67 years), mean BMI was 27.0±4.8 kg/m², 28.1% were obese (BMI ≥ 30), 33.2% were current smokers, 22.7% reported hypertension and 4.0% reported diabetes.

The mean sleep duration was 6.9±1.0 hours per night. Overall, the majority of subjects (88.1%) were normal sleepers (reporting sleeping 6–9 hours per night). Short sleepers (<6 hours per night) and long sleepers (≥9 hours per night) were 387 (7.6%) and 217 (4.3%) of the sample, respectively. Compared with short sleepers, normal sleepers were younger, had a lower BMI, were less likely to smoke, report hypertension or diabetes and were more likely to be married and to report exercising regularly. Additionally, short sleepers had a higher prevalence of diabetes, hypertension and depression as compared with normal sleepers. Long sleepers were older, more likely to be females, had a higher BMI, were less likely to be married and had a higher prevalence of diabetes and depression as compared with normal sleepers (table 1).

The box plot in figure 1 shows the median number of hours slept per night and the range of reported sleep duration in the different centres in the study. Even though the median is the same between all centres (7 hours), there was a considerable variation in range and reported mean sleep duration between centres, ranging from 6.4 in Huelva, Spain, to 7.1 hours per night in Reykjavik, Iceland (p<0.0001) (see figure 1).

There was also a considerable difference between centres in the prevalence of being a short sleeper (the lowest was 2% in Aarhus, Denmark, and the highest was 20.7% in Huelva, Spain) (figure 2). The prevalence of long sleepers varied from 1.7% in Bergen, Norway, to 9.8% in Oviedo, Spain.

**SLEEP LENGTH AND RESPIRATORY SYMPTOMS**

All respiratory symptoms were more common in short sleepers as compared with normal sleepers (table 2). The prevalence of reporting having a blocked nose was also higher among short sleepers as compared with normal sleepers. Furthermore, short sleepers had a higher reported prevalence of nGOR and COPD as compared with normal sleepers. The only significant difference between long sleepers and normal sleepers was a higher prevalence of reporting shortness of breath after strenuous activity in long sleepers (table 2).

In the adjusted model, short sleep was associated to all respiratory and nasal symptoms except ever asthma and nasal allergies when the adjustment was without BMI. When BMI was also adjusted for, all symptoms except asthma were still associated with short sleep. Only a few symptoms were associated with long sleep duration (table 3).

The pooled estimates of the meta analyses of the association between short sleep and the respiratory variables were very similar to those found in table 3 (data not shown). No significant heterogeneity between the centres was found with the exception of the association between short sleep and shortness of breath following activity (p_{heterogeneity}=0.04), being woken by cough (p_{heterogeneity}=0.01) and cough during day and night in the winter (p_{heterogeneity}=0.03).

Figure 2  The prevalence (%) of being a short sleeper in different centres. Centres are sorted by latitude (from North to South).
Our results show that short sleep duration is associated with many common respiratory symptoms and that this relationship is independent of obesity.

Given the known relationship between sleep duration and obesity, and obesity and respiratory symptoms, our hypothesis was that obesity was an important mediator to a possible association between sleep duration and respiratory symptoms. Interestingly, we found a significant relationship between short sleep duration and respiratory symptoms independent of obesity.

Previous studies have shown a strong relationship between sleep duration and obesity, and hypertension and CVD. A recent study by Patel et al found that short sleep duration was significantly associated with obesity with an OR of 1.29 (95% CI 1.12 to 1.49) and a recent meta-analysis showed a U-shaped dose–response relationship between extremes of sleep duration and metabolic syndrome. Metabolic syndrome has also been shown to be an independent risk factor for worsening of respiratory symptoms, lung function impairment and asthma.

In our analysis, we made adjustments with and without BMI in order to better understand the role of BMI in the associations of sleep length and respiratory symptoms. We also divided our sample into two groups, a group with BMI <30 and BMI ≥30. We found in both groups a significant relationship between short sleep and respiratory symptoms. The high prevalence of respiratory symptoms associated with short sleep is therefore unlikely to be driven by the known associations of short sleep and obesity.

Our hypothesis was that obesity was a mediator in the relationship between sleep duration and respiratory symptoms. However, our results indicate a direct relationship not mediated by BMI. It is possible that respiratory symptoms are directly disrupting sleep (people waking up because of coughing, blocked nose, and so on). Others have reported associations between sleep disturbances and respiratory disorders. Klink and Quan found that individuals with asthma and bronchitis reported a high prevalence of difficulties initiating and maintaining sleep as well as daytime sleepiness. Leng et al recently reported an association of excessive daytime napping with increased respiratory symptoms. In another general
population study, specific respiratory symptoms such as coughing and wheezing were more predictive of sleep complaints than lung function or diagnosis of a lung disease.28 Furthermore, patients with COPD often experience sleep problems that lead to impaired quality of life.29 We have previously reported an association between asthma and reduced sleep quality and increased daytime sleepiness,30 31 and an association between asthma and short sleep duration. Our results indicate that sleep might directly impact sleep quality and increase the risk of respiratory symptoms and disorders. Others have reported associations between respiratory symptoms and insomnia.34 35 It is however important to note that short sleepers in our study were more likely to smoke and even though we adjusted for this in our analysis this could account for some of the increase in respiratory symptoms in this group.

A relationship between untreated OSA and difficulties maintaining sleep has also been shown,36 where nighttime awakenings improve if OSA is treated,37 which supports the theory of respiratory disorders disrupting sleep. Short sleep could therefore be a marker of OSA, which is known to be associated to nGOR and other respiratory symptoms.38 Other studies have shown an association between OSA and short sleep duration.39 The subjects in our study from the Icelandic centre did however all have an overnight sleep study where OSA was estimated40 and those who were diagnosed with OSA did not report shorter sleep than the other subjects.

Respiratory symptoms have so far not been the main focus in studies on causal pathways of short sleep duration, but given our results some respiratory symptoms might directly impact sleep quality and increase the risk of short sleep duration. Our results indicate that sleep length needs to be one of the variables studied when exploring respiratory symptoms, and it may also be important for clinician working with respiratory patients to ask about their sleep habits.

In the present study, we also found that being a long sleeper was associated with a few respiratory symptoms and disorders. Others have reported associations between having asthma and being a long sleeper,41 which we replicated in this study among subjects with BMI ≥30 only. Many previous studies have also shown a strong association between long sleep, depression and increased mortality.42 43 The reason for the association between these respiratory symptoms and long sleep is not clear. It is possible that those with a history of respiratory

symptoms are more unwell and less active, which could facilitate longer sleep. Also, increased inflammation and elevated cytokines among subjects with respiratory symptoms could lead to increased fatigue and hence produce longer sleep. Our results show that short sleep is much more strongly related to respiratory symptoms than long sleep, but these associations need to be studied further.

There were considerable differences in sleep duration in different centres in our study and the highest percentage of short sleepers were in the Spanish centres. Cultural differences, such as siestas or afternoon napping, may impact sleep duration.

There are several limitation of this study that need to be considered. Our results are from a cross-sectional study, and deeper understanding of the underlying causal pathways can only come from prospective or intervention studies. Information regarding sleep duration was self-reported without any objective measure on sleep time. However, sleep length, as reported in questionnaires, correlates well with sleep diaries. Also, most symptoms were reported as present for the past 12 months, and therefore it is not clear if these symptoms were currently present when the study took place. Furthermore, we did not have information on daytime napping, which could affect nighttime sleep length. The strengths of this study include the population-based nature of this large sample from many centres in 10 different countries and the use of standardised and validated procedures and instruments.

To summarise, our results show that reporting respiratory symptoms is related to sleep duration, especially with reported short sleep. Short sleepers report more respiratory symptoms, and this association is not confined to those who are obese. To our knowledge, this is the first report of an association between respiratory symptoms and sleep length in a large population-based cohort of middle-aged subjects. There is a need for prospective studies on sleep length and respiratory symptoms in order to clarify how short and/or long sleep are associated to respiratory health.
