LDCT lung cancer screening in populations at different risk for lung cancer

Gustavo Borges da Silva Teles, Ana Carolina Sandoval Macedo, Rodrigo Caruso Chate, Viviane Arevalo Tabone Valente, Marcelo Buarque de Gusmao Funari, Gilberto Szarf

ABSTRACT

Introduction The improvement of low-dose CT (LDCT) lung cancer screening selection criteria could help to include more individuals who have lung cancer, or in whom lung cancer will develop, while avoiding significant cost increase. We evaluated baseline results of LDCT lung cancer screening in a population with a heterogeneous risk profile for lung cancer.

Methods LDCT lung cancer screening was implemented alongside a preventive health programme in a private hospital in Brazil. Individuals older than 45 years, smokers and former smokers, regardless of tobacco exposure, were included. Patients were classified according to the National Lung Screening Trial (NLST) eligibility criteria and to PLCOm2012 6-year lung cancer risk. Patient characteristics, CT positivity rate, detection rate of lung cancer and false-positive rate were assessed.

Results LDCT scans of 472 patients were evaluated and three lung adenocarcinomas were diagnosed. CT positivity rate (Lung-RADS 3/4) was significantly higher (p=0.019) in the NLST group (10.1% (95% CI, 5.9% to 16.9%)) than in the non-NLST group (3.6% (95% CI, 2.62% to 4.83%)) and in the PLCOm2012 high-risk group (14.3% (95% CI, 6.8% to 27.7%)) than in the PLCOm2012 low-risk group (3.7% (95% CI, 2.9% to 4.8%)) (p=0.016). Detection rate of lung cancer was also significantly higher (p=0.018) among PLCOm2012 high-risk patients (5.7% (95% CI, 2.5% to 12.6%)) than in the PLCOm2012 low-risk individuals (0.2% (95% CI, 0.1% to 1.1%)). The false-positive rate for NLST criteria (16.4% (95% CI, 13.2% to 20.1%)) was higher (p<0.001) than for PLCOm2012 criteria (7.6 (95% CI, 5.3% to 10.5%)).

Discussion Our study indicates a lower performance when screening low-risk individuals in comparison to screening patients meeting NLST criteria and PLCOm2012 6-year lung cancer risk. Also, incorporating PLCOm2012 6-year lung cancer risk (≥0.0151) as an eligibility criterion seems to increase lung cancer screening effectiveness.

INTRODUCTION

The National Lung Screening Trial (NLST) demonstrated a 20% reduction in lung cancer mortality for screening with low-dose CT (LDCT) versus chest radiography using age and smoking exposure as selection criteria for lung cancer screening. However, only 26.7% of all individuals currently being diagnosed with lung cancer in the USA meet the strict NLST eligibility criteria. Accordingly, there is a need to improve screening selection criteria in order to select more individuals who have lung cancer, or in whom lung cancer will develop, while avoiding significant cost increase.

Some risk assessment models that incorporate additional risk factors have been developed and demonstrated to improve lung cancer screening efficiency in North America and the UK, including PLCOm2012 and Liverpool Lung Project Model. The performance of these models has been evaluated in several studies in the USA, UK, Canada, Germany and Australia, but have not been validated in South America. Also, LDCT positivity has been recently demonstrated as an independent risk factor for future lung cancer in high-risk individuals. Having at least one positive screen is associated with increased PLCOm2012 6-year lung cancer risk and improved lung cancer risk prediction.
We compared baseline results of LDCT lung cancer screening in a population with a heterogeneous risk profile for lung cancer in Brazil, according to NLST criteria and to PLCOm2012 6-year lung cancer risk.

METHODS
LDCT lung cancer screening was implemented alongside a preventive health programme in a private hospital in Brazil, where cardiovascular risk and respiratory symptoms were assessed. After discussing harms and benefits, individuals older than 45 years, smokers and former smokers, regardless of tobacco exposure, were offered participation in the screening.

Baseline LDCT scans performed from May 2015 to April 2016 were reviewed. CT scans were reported by board-certified thoracic radiologists and examinations were interpreted using Lung-RADS 1.0 classification. Patients with CT positive results (Lung-RADS 3 and 4) were referred to a pulmonologist. Patients with other potentially clinically significant findings (Lung-RADS S category) were referred to their clinicians. Lung cancer data were acquired from direct contact with patients.

COPD, chronic obstructive pulmonary disease; NLST, National Lung Screening Trial.

Patient and public involvement
Patients or other external influences had no involvement in the design and conduct of this study, in the writing of the manuscript and in decision-making regarding publishing the article.

**RESULTS**
The preventive health programme included 4911 patients, 1165 (23.7%) of which were offered participation in the lung cancer screening programme; 472 patients (40.5%) underwent LDCT scans. Baseline characteristics according to NLST criteria are detailed in
McNemar’s test (McNemar’s test is used to compare paired proportions). NLST, National Lung Screening Trial.

Table 1. Seventy-nine patients (16.7%) met NLST criteria (mean age: 60.6 years (±5.2); median tobacco exposure: 40 pack-years (IQR 31–60) and 393 patients (83.3%) were included in the non-NLST group (mean age: 48.7 years (±8.7); median tobacco exposure: 15 pack-years (IQR 7.5–25)).

There were no statistically significant differences between the groups regarding sex, race, smoking status and body mass index. Educational information was obtained from 438 patients (92.8%). The NLST group had a significantly lower educational level compared with the non-NLST group.

Thirty-five patients (8.0%) were included in the PLCO<sub>m2012</sub> high-risk group and 403 patients (92.0%) were considered PLCO<sub>m2012</sub> low-risk individuals. Baseline characteristics stratified by PLCO<sub>m2012</sub> 6-year lung cancer risk are detailed in Table 2. The correlation between groups according to NLST criteria and PLCO<sub>m2012</sub> 6-year lung cancer risk is described in Table 3.

The CT positivity rate was 10.1% (95% CI: 5.9% to 16.9%) in the NLST group, significantly higher (p=0.019) than in the non-NLST group (3.6% (95% CI: 2.62% to 4.83%)) (Table 4).

CT positivity rate was 14.3% (95% CI: 6.8% to 27.7%) in patients with PLCO<sub>m2012</sub> high risk, also significantly higher (p=0.016) than in patients with PLCO<sub>m2012</sub> low risk (3.7% (95% CI: 2.9% to 4.8%)) (Table 5).

Three lung adenocarcinomas were diagnosed after baseline LDCT results (Figure 1). The detection rate of lung cancer among NLST patients (2.5% (95% CI: 1.1% to 5.6%)) was higher than in non-NLST patients (0.3% (95% CI: 0.1% to 1.3%)), but not statistically significant (p=0.070) (Table 6).

Detection rate of lung cancer in PLCO<sub>m2012</sub> high-risk patients (5.7% (95% CI: 2.5% to 12.6%)) was significantly higher (p=0.018) than in the PLCO<sub>m2012</sub> low-risk group (0.2% (95% CI: 0.1% to 1.1%)) (Table 7).

The false-positive rate for NLST criteria was 16.4% (95% CI: 13.2% to 20.1%), significantly higher (p<0.001) than for PLCO<sub>m2012</sub> criteria (7.6% (95% CI: 5.3% to 10.5%)).

**DISCUSSION**

Our study compared LDCT screening in populations at different lung cancer risk and found low baseline detection rates of lung cancer in low-risk populations (0.3% in non-NLST individuals and 0.2% in the PLCO<sub>m2012</sub> low-risk group). Only a few studies evaluated LDCT screening in populations at low risk for lung cancer, almost exclusively in Asia. A screening study in China that included never smokers (most of them women) found lung cancer detection rate among never smokers (0.34%) to be higher compared with the group of smokers (including second-hand smokers and low-intensity smokers). The authors explain this because there are far more non-smokers female lung adenocarcinomas patients in East Asia than in Europe and the USA, often associated with *EGFR* gene mutations.

The baseline detection rate of lung cancer among individuals meeting NLST criteria in our study (2.5%) was higher than other studies, such as NLST (1.0%), NELSON (0.9%) and BRELT1 (1.3%), the latter being the only CT screening study conducted in Brazil, which included patients meeting NLST criteria. One possible explanation for that may be related to the small number of patients at high risk in our study.

Our Lung-RADS CT positivity rate was 10.1% in the NLST group and 3.6% in the non-NLST population, 14.3% in PLCO<sub>m2012</sub> high-risk group and 3.7% in the PLCO<sub>m2012</sub> low-risk group. Pinsky et al found a similar positivity rate in high-risk individuals applying Lung-RADS to the NLST population (13.6%). To our knowledge, no other study has evaluated CT screening positivity rate in low-risk individuals using the Lung-RADS classification.

The use of PLCO<sub>m2012</sub> 6-year lung cancer risk as an eligibility criterion demonstrated to improve lung cancer screening efficiency compared with NLST criteria in North America. Crobbie et al also used PLCO<sub>m2012</sub> 6-year criteria for lung cancer screening in the United States.
lungs cancer risk ≥0.0151 to target high-risk individuals in deprived areas of Manchester and found a high prevalence of lung cancer (3%). In our study, the use of PLCO_m2012 6-year lung cancer risk for defining the high-risk group has shown to increase CT positivity and lung cancer detection rate. Furthermore, the false-positive rate for PLCO_m2012 criteria was lower than for NLST criteria, indicating an improvement of screening efficiency, even in a country with a high incidence of granulomatous disease as Brazil.

This study has limitations. First, it included a relatively small screening population. Second, it included only baseline LDCT examinations. Therefore, it was not possible to evaluate interval lung cancer incidence or accurately assess false-negative results.

A number of factors need to be taken into consideration in making decisions about implementing LDCT lung cancer screening in communities, including eligibility criteria, CT positivity and false-positive results, which may have a great impact on the cost-effectiveness of the programme. Previous studies have shown that patients at higher risk for lung cancer achieve the greatest benefit of screening related to lung cancer mortality.

Our study indicates that the screening yield of low-risk individuals is lower in comparison with high-risk patients, as CT positivity and lung cancer detection rate were significantly lower in the low risk groups. As a result, screening low-risk patients could lead to a higher number of CT scans, due to its lower diagnostic yield, resulting in increased costs compared with screening a high-risk population. On the other side, incorporating PLCO_m2012 6-year lung cancer risk ≥0.0151 as an eligibility criterion seems to increase lung cancer screening effectiveness.
