ABSTRACT

Background Long-term exposure to ambient air pollution leads to respiratory morbidity and mortality; however, the evidence of the effect on lung function and chronic obstructive pulmonary disease (COPD) in older adult populations is inconsistent.

Objective To address this knowledge gap, we investigated the associations between particulate matter (PM), nitrogen dioxide (NO₂) exposure and lung function, as well as COPD prevalence, in older Chinese adults.

Methods We used data from the WHO Study on global AGEing and adult health (SAGE) China Wave 1, which includes 11,693 participants from 64 townships in China. A cross-sectional analysis explored the association between satellite-based air pollution exposure estimates (PM with an aerodynamic diameter of ≤10 μm [PM₁₀], ≤2.5 μm [PM_{2.5}] and NO₂) and forced expiratory volume in one second (FEV₁), forced vital capacity (FVC), the FEV₁/FVC ratio and COPD (defined as post-bronchodilator FEV₁/FVC <70%). Data on lung function changes were further stratified by COPD status.

Results Higher exposure to each pollutant was associated with lower lung function. An IQR (26.1 μg/m³) increase in PM_{2.5} was associated with lower FEV₁ (−71.88 mL, 95% CI −92.13 to −51.64) and FEV₁/FVC (−2.81, 95% CI −3.37 to −2.25). For NO₂, an IQR increment of 26.8 μg/m³ was associated with decreases in FEV₁ (−60.12 mL, 95% CI −84.00 to −36.23) and FVC (−32.33 mL, 95% CI −56.35 to −8.32). A 31.2 μg/m³ IQR increase in PM₁₀ was linked to reduced FEV₁ (−8.86 mL, 95% CI −5.40 to 23.11) and FEV₁/FVC (−1.85, 95% CI −2.24 to −1.46). These associations were stronger for participants with COPD. Also, COPD prevalence was linked to higher levels of PM_{2.5} (POR 1.35, 95% CI 1.26 to 1.43), PM₁₀ (POR 1.24, 95% CI 1.18 to 1.29) and NO₂ (POR 1.04, 95% CI 0.98 to 1.11).

Conclusion Ambient air pollution was associated with lower lung function, especially in individuals with COPD, and increased COPD prevalence in older Chinese adults.

INTRODUCTION

Air pollution represents a significant public health threat, causing over 4 million premature deaths worldwide.¹ The full list of medical conditions either mediated or caused

Key messages

- To explore and quantify the association between common outdoor air pollutants and chronic obstructive pulmonary disease (COPD) prevalence, as well as lung function, in older individuals from China with and without COPD.
- Long-term exposure to ambient particulate matter (with an aerodynamic diameter of ≤10 μm [PM₁₀] and ≤2.5 μm [PM_{2.5}]) and NO₂ was observed to be associated with a higher prevalence of COPD among older Chinese adults. Detrimental changes in lung function parameters (forced expiratory volume in one second (FEV₁), forced vital capacity (FVC) and FEV₁/FVC) were also associated with increased levels of PM_{2.5}, PM₁₀ and NO₂, and were found to be more significant in participants with COPD.
- This population-based cross-sectional analysis is one of the first studies to suggest that people with COPD might be at a higher risk of decrements in lung function associated with ambient air pollution exposure. The findings also highlight the role of outdoor air pollution exposure in relation to the prevalence of COPD among older adults from developing countries.

directly by ambient air pollution is long and is a subject of active research.^{2,3} Yet some of the first and best-established health effects attributed to air pollution are those affecting the respiratory system.⁴ According to data from the Global Burden of Disease study, 43% of lung diseases, including lung cancer, chronic obstructive pulmonary disease (COPD) and lower respiratory infections, are attributed to elevated levels of air pollutants leading to more than 1.8 million annual deaths.⁵ COPD is one of the leading causes of death and disability globally,⁶ with an estimated worldwide prevalence of 10%.⁷ It has been established that both indoor and outdoor air pollution worsen COPD.^{7,8}

A large proportion of deaths related to both ambient air pollution and airway diseases

occur in low-income and middle-income countries, where rapid economic development resulting in active infrastructure building, mining and urbanisation results in some of the highest levels of air pollution in the world.⁹ China, for example, has undergone a period of rapid industrialisation that has resulted in massive increases in emissions of various air pollutants.¹⁰ According to the WHO database of air pollution monitoring, 283 of the top 500 polluted cities in the world are found in China.¹¹ Furthermore, the vast majority of Chinese cities fail to meet the air quality guidelines recommended by the WHO.¹²

Older adults are known to be more susceptible to the detrimental health effects of air pollution.¹³ This age group has a higher incidence and prevalence of chronic, progressive lung disorders, such as COPD.^{8 14} These factors make older adults particularly susceptible to suffering from rapid urbanisation and increased air pollution emissions.

Although the association between ambient air pollution and impaired lung function as well as COPD seems logical and intuitive given the clear associations with a broad range of respiratory mortality and morbidity outcomes, the data regarding the type of pollutants and clinical endpoints have not been consistently measured. For example, air pollutants have been associated with various degrees of lung function impairment and COPD worsening in some publications,^{15 16} whereas others failed to find any significant links between the exposure and the outcome.^{17 18} The heterogeneity of the results from previous studies can be partially explained by variations in population sampling methods, exposure estimation techniques, and measurement and control of important confounders. The lack of studies coming from developing countries, including China, is one of the most significant gaps in the data. To address these limitations in the existing literature, we aimed to investigate the long-term effects of outdoor air pollution on the lung function and COPD prevalence in a nationally representative population of older Chinese adults.

METHODS

Study population

The WHO Study on global AGEing and adult health (SAGE) is a nationally representative, cross-sectional survey of China. Full details on the study methodology are available elsewhere.¹⁹ Briefly, in the SAGE China survey, information was collected from Chinese adult respondents through an interview between 2007 and 2010.¹⁹ As a result of a multistage random sampling strategy, a total of 11 693 adult participants, aged 50 years and older, were ultimately included in the analysis (Figure S1).

Patient involvement

The study design, analysis, interpretation of the results and the writing or editing of this research paper were made without patient involvement.

Outcome measurement

As part of SAGE China Wave 1, lung function tests were performed using a MIR SpiroDoc Diagnostic Portable Spirometer (Medical International Research, Rome, Italy). Participants were instructed to wear a nose clip, and tests were conducted in a sitting position until three satisfactory spirometric measurements were obtained.²⁰ Forced vital capacity (FVC), forced expiratory volume in one second (FEV₁) and the FEV₁/FVC ratio were calculated from the averages of the three readings. COPD was defined as a post-bronchodilator FEV₁/FVC less than 70%.²¹

Exposure assessment

Data concentrations of particulate matter (PM) and nitrogen dioxide (NO₂) were predicted through models using combined data from satellite remote sensing, meteorology, land use information and ground monitoring on the pollutants from stations throughout China. From 2004 to 2016, measurements of pollutants' daily ground-level concentrations were obtained from 1479 stations of the China National Environmental Monitoring Centre. A detailed description of PM and NO₂ predictions from these models has been published previously.^{22–24}

Using the monitor data, 10-fold validation was applied to evaluate the predictive ability of the models for both PM and NO₂. The adjusted coefficient of determination (R²) and root-mean-squared error are presented in online supplemental table S1.

Exposure to long-term outdoor air pollution was defined as the average concentration of PM and NO₂ for the 3 years (2005–2007). Lastly, we geocoded the community locations of participants and linked these to the estimated annual concentrations of PM and NO₂.

Covariates

Demographic, behavioural and socioeconomic confounders and potential effect modifiers were identified a priori through a literature search.^{25 26} Demographic confounders included age, sex, body mass index (BMI) and marital status. Behavioural variables were smoking status (never, current, former), and tobacco consumption (mean daily tobacco consumption), alcohol use (never or ever), fruit and vegetable consumption (sufficient and insufficient), and physical activity (low, moderate and high). Socioeconomic variables involved education level and household income. The level of education based on the participants' self-reporting was divided into the following categories: (1) no formal education, (2) primary school, (3) middle school, (4) college or higher. Household income was categorised into two levels (low or high) using a median income of 15 000 Chinese yuan (¥) as a threshold. Additionally, we considered the place of residence as either urban or rural. Domestic fuel type

was included as an indicator of indoor air pollution. Two fuel types were mainly used: clean fuels, including electricity and natural gas, and unclean fuels, such as coal, wood, dung and agricultural residues.

Statistical analysis

We examined the association between lung function metrics and an IQR increase in 3-year moving averages of PM_{10} , $PM_{2.5}$ and NO_2 in single pollutant models. To assess for potential dependence in lung function measurements for participants in the same community, data clustering was accounted using a two-level linear regression model, where participants were considered as the first-level unit and the community as the second-level unit. The effect estimates were expressed as absolute differences in lung function measures associated with each IQR ($\mu\text{g}/\text{m}^3$) increase in ambient $PM_{2.5}$, PM_{10} or NO_2 concentrations.

For models using COPD as an outcome, logistic regression may overestimate the prevalence ratio, given a high prevalence of COPD in the study sample (19.5%). Therefore, we used a modified Poisson regression with robust error variance to directly estimate the prevalence OR of COPD. In fully adjusted models, we controlled for age, sex, BMI, smoking status (never, current, former), tobacco consumption, physical activity, education level, daily fruit and vegetable intake, alcohol use, place of residence, type of fuel used at home and median annual household income. Additionally, several variables were investigated as potential effect modifiers (age, sex, smoking and asthma history, and household income). Interactions were assessed by including multiplicative terms between pollutant variables and several potential effect modifiers into the models. Significance of effect modification was determined if the p value for the hypothesis test of the interaction was <0.01 .

Sensitivity analyses were performed. First, average pollutants concentrations were used for 1 and 5 years before the baseline survey to ensure that our results were not being driven primarily by our selection of an exposure window. Second, we excluded the participants with cardiovascular diseases and additionally adjusted for city-specific covariates, such as gross domestic product (GDP) and percentage of the population living in urban areas. All analyses were conducted using STATA V.15 (StataCorp, College Station, Texas, USA) and p value <0.05 was used to determine statistical significance.

RESULTS

Characteristics for participants with complete data in fully adjusted lung function models are summarised in table 1. The mean age of participants with COPD was 64 years, and 61 for participants without COPD. About 51% of the participants were female, and the majority were living in rural areas (57%), reported never smoking (63%), and came from households earning less than ¥15 000 annually (54%). Some 3.5% of study subjects had been previously diagnosed with asthma, and 52%

were currently using unclean fuel at their homes. Lastly, COPD prevalence was 19.5%.

Online supplemental table S2, figures S1–S3 show the distribution of residential ambient air pollution concentrations. Mean (\pm SD) annual estimates of PM_{10} , $PM_{2.5}$ and NO_2 were 91.11 (\pm 28.95 $\mu\text{g}/\text{m}^3$), 54.02 (\pm 17.02 $\mu\text{g}/\text{m}^3$) and 28.97 (\pm 22.42 $\mu\text{g}/\text{m}^3$), respectively. NO_2 concentrations were highly correlated with $PM_{2.5}$ ($r=0.92$), but less so with PM_{10} .

Lung function and air pollution: full cohort

In the full cohort, including both non-COPD and COPD participants, an IQR increase in the 3-year moving average of all pollutants showed adverse associations with lung function (table 2). In adjusted models, an IQR increase in PM_{10} exposure was associated with lower FEV_1 (-29.08 mL, 95% CI -43.26 to -14.89) and FEV_1/FVC ratio (-1.85 , 95% CI -2.24 to -1.46). For each IQR increase in NO_2 , lower FEV_1 (-60.12 mL, 95% CI -84.00 to -36.23) and FVC (-32.33 mL, 95% CI -56.35 to -8.32) was observed. Furthermore, results showed negative associations between $PM_{2.5}$ concentrations and lung function, with stronger effects on FEV_1 than FVC. The FEV_1/FVC ratio showed no association with ambient NO_2 exposure. For all pollutants, significant effect modification by BMI and lower household income was identified (all $P_{\text{interact}} <0.001$). For NO_2 and PM_{10} , older age (>65 years) was linked with lower FEV_1 . Associations were further investigated in non-COPD and COPD participants separately.

COPD and air pollution

Consistent with our findings for lung function, we found an IQR increase in the 3-year moving average of $PM_{2.5}$ and PM_{10} to be associated with 35% and 24% increased prevalence odds ratio (POR) of COPD (POR 1.35, 95% CI 1.26 to 1.43; POR 1.24, 95% CI 1.18 to 1.29), respectively, when COPD status was treated as a binary outcome (figure 1). A nominally positive, non-significant, association was observed for NO_2 . Effect modification for $PM_{2.5}$ was seen in former smokers ($p=0.04$).

Lung function and air pollution: non-COPD participants

In participants without COPD, an IQR increase in each pollutant showed significant inverse associations with FEV_1 (PM_{10} -25.31 , β 95% CI -36.81 to -13.8 ; $PM_{2.5}$ -53.81 , β 95% CI -107.09 to -0.53 ; and NO_2 -74.88 , β 95% CI -146.61 to -3.15). However, an IQR increment in 3-year moving averages of PM_{10} , $PM_{2.5}$ and NO_2 was not significantly associated with FVC (table 3).

Lung function and air pollution: COPD participants

In participants with COPD, all pollutants were statistically significantly associated with decrements in FEV_1 and FVC. Additionally, the magnitude of association was more substantial than that found in non-COPD participants (table 3), with an IQR increase in PM_{10} ,

Table 1 Population baseline characteristics

	No COPD±SD or %	COPD±SD or %	Total population	Difference p value

BMI, body mass index; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; NO₂, nitrogendioxide; PM₁₀, particulate matter with an aerodynamic diameter ≤10 µm; PM_{2.5}, particulate matter with anaerodynamic diameter ≤2.5 µm.

PM_{2.5} and NO₂ associated with FEV₁ -25.31 mL (95% CI -36.81 to -13.80), -53.81 mL (95% CI -107.09 to -0.53) and -74.88 mL (95% CI -146.61 to -3.15), respectively. Smaller magnitudes of association were observed in FVC measurement (table 3).

Results of PM₁₀, PM_{2.5} and NO₂ subgroup analyses for COPD and FEV₁ are shown in tables 4 and 5, respectively.

FEV₁-stratified analyses showed stronger associations for PM₁₀ and NO₂ in older participants, subjects from lower-income households, and individuals with a history of asthma. The same effect modification patterns were observed for FVC-stratified analyses (data not shown). Participants from lower-income households had mean FEV₁ levels three-to-five times lower than higher-income

Table 2 Associations of lung function and ambient air pollution exposure

Pollutant	FEV ₁ (mL) β (95% CI)	FVC (mL) β (95% CI)	FEV ₁ /FVC (%) β (95% CI)
PM ₁₀	-29.08 (-43.26 to 14.89)*	-8.86 (-5.40 to 23.11)	-1.85 (-2.24 to -1.46)*
PM _{2.5}	-71.88 (-92.13 to 51.64)*	-11.26 (-31.64 to 9.11)	-2.81 (-3.37 to -2.25)*
NO ₂	-60.12 (-84.00 to 36.23)*	-32.33 (-56.35 to 8.32)*	-0.39 (-1.05 to 0.28)

*p<0.05. Models adjusted for age, sex, smoking status, daily tobacco consumption, physical activity, education, BMI, alcohol, place of residence, household income, type of indoor fuel use, daily fruit and vegetables consumption. BMI, body mass index; NO₂, nitrogen dioxide; PM₁₀, particulate matter with an aerodynamic diameter less than or equal to 10 µm; PM_{2.5}, particulate matter with an aerodynamic diameter less than or equal to 2.5 µm.

participants (all p<0.001); individuals with a history of asthma showed FEV₁ levels lower than those with no previous history of asthma, per unit increase in PM₁₀, PM_{2.5} or NO₂, although the later findings did not reach statistical significance. In COPD subgroup analyses, NO₂ association was also found to be stronger among participants with asthma (p=0.003).

Our sensitivity analyses produced comparable effect estimates to our main models (online supplemental tables S3 and S4). When using different exposure windows and additionally adjusting for city-specific covariates, such as GDP, percentage of the population living in urban areas, similar effect estimates were observed. For instance, each IQR increase in the 1-year average concentration of PM₁₀ was associated with a reduction in FEV₁ (β -34.44, 95% CI -46.09 to -22.79) and an increase in COPD prevalence by 30% (POR 1.30, 95% CI 1.21 to 1.39). When excluding the participants with cardiovascular diseases, the models also produced consistent effect estimates (online supplemental tables S3 and S4).

DISCUSSION

Long-term exposure to higher concentrations of PM_{2.5} and PM₁₀ was associated with increased prevalence of COPD among older Chinese adults. Impaired lung function related to air pollution exposure was also observed. Reduced FEV₁ was linked to all three pollutants; PM_{2.5} and PM₁₀ were additionally associated with decreased FEV₁/FVC ratio, while NO₂ was associated with lower FVC. We further found more significant magnitude effect

estimates among participants with COPD, suggesting that this may be a particularly susceptible group to the deleterious pulmonary effects of air pollution.

COPD prevalence

Air pollution has been recognised as a likely risk factor for COPD, although only a small number of studies have investigated this association in China.²¹ A cross-sectional study of almost 6000 residents of Guangdong province showed statistically significant associations between elevated levels of PM_{2.5} and PM₁₀ and increased prevalence of COPD.²⁷ For daily mean PM_{2.5}>75 mg/m³ and PM₁₀>50 to ≤150 mg/m³, the adjusted OR for COPD prevalence was 2.530 (95% CI 1.280 to 5.001) and 2.442 (95% CI 1.449 to 4.117), respectively. Accordingly, the present population-based analysis showed 35% (POR 1.35, 95% CI 1.26 to 1.43) and 24% (POR 1.24, 95% CI 1.18 to 1.29) increase in COPD prevalence due to high exposure to PM_{2.5} and PM₁₀, respectively. Presumably, the difference in prevalence is due to distinct distribution of study populations. Likewise, in a large-scale (n=285 046) longitudinal cohort with 13 years of follow-up, Guo *et al* found a higher incidence of COPD among those exposed to higher PM_{2.5} concentrations.²⁸

The negative effect of the long-term exposures to PM_{2.5} and PM₁₀ is further supported by the results from Western countries^{29 30}; however, findings regarding COPD and air pollution are not consistent. For example, a meta-analysis of four large European cohorts did not demonstrate any significant associations between prevalence and incidence of COPD and different air pollutants.³¹ We found no significant associations of COPD prevalence with NO₂, which contradicts the findings from the UK Biobank study and a US cohort study.^{29 30}

This heterogeneity in findings may be explained by different outcome and exposure assessments, or uncontrolled confounding in some studies. Most of the evidence supporting the positive association between NO₂ and COPD incidence or prevalence is derived from research on the general population of adults from Western countries,³² whereas we evaluated older adults from China. Also, the

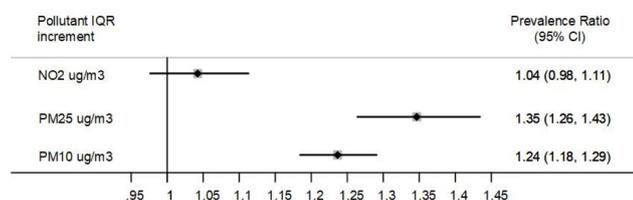

Figure 1 Association between chronic obstructive pulmonary disease prevalence ratio and ambient air pollution exposure.

Table 3 Air pollution exposure in patients with COPD and without COPD

Type of pollutant	FEV ₁ (mL) β (95% CI)		FVC (mL) β (95% CI)	
	COPD	No COPD	COPD	No COPD
PM ₁₀	-25.31 (-36.81 to 13.80)*	-2.81 (-17.69 to 12.07)	-15.34 (-53.32 to 22.65)	16.73 (-32.15 to 1.32)
PM _{2.5}	-53.81 (-107.09 to 0.53)*	-39.00 (-60.02 to 17.98)*	-55.36 (-111.48 to 0.77)	1.42 (-20.37 to 23.22)
NO ₂	-74.88 (-146.61 to 3.15)*	-49.30 (-73.13 to 25.47)*	-82.42 (-157.97 to 6.86)*	-17.72 (-42.44 to 6.99)

*p<0.05. Models adjusted for age, sex, smoking status, daily tobacco consumption, physical activity, education, BMI, alcohol, place of residence, household income, type of indoor fuel use, daily fruit and vegetables consumption. IQR PM₁₀: 3 years: 31.2 µg/m³; IQR PM_{2.5}: 3 years: 26.1 µg/m³; IQR NO₂: 3 years: 26.8 µg/m³.

BMI, body mass index; NO₂, nitrogen dioxide; PM₁₀, particulate matter with an aerodynamic diameter less than or equal to 10 µm; PM_{2.5}, particulate matter with an aerodynamic diameter less than or equal to 2.5 µm.

NO₂ association may be more susceptible to confounding due to NO₂ being primarily a traffic-related air pollutant with high spatial variation and people having a much greater variability in traffic-related pollution exposure than PM. Thus, geographic and population-related factors might have impacted the magnitude of the effect.

Lung function

Long-term exposure to air pollution has also been previously shown in some, but not all, studies to adversely affect lung function. Subjects from our cohort demonstrated an obstructive pattern of lung function decline,³³ with significant associations between FEV₁ reduction and PM_{2.5}, PM₁₀ and NO₂ exposures, as well as FEV₁/FVC decrease and exposure to PM_{2.5} and PM₁₀. The associations we observed for FEV₁ are broadly consistent with the outcomes reported by other studies from economically developing countries^{27 28 34} as well as some European studies.^{28 35–38} However, a meta-analysis of European multicentre cohort studies (ESCAPE) showed no associations between PM_{2.5} and decrements in FEV₁.³⁵

Our findings regarding the decrease in FEV₁/FVC ratio with increased PM exposure have also recently been reported in some Asian cohorts.^{27 28 34} Liu *et al* demonstrated 0.09% (95% CI -0.170 to -0.010) and 0.024% (95% CI -0.092 to 0.040) declines in FEV₁/FVC ratio for PM_{2.5} and PM₁₀ exposure, respectively, among Chinese adult participants.²⁷ A large longitudinal Taiwanese cohort showed a 0.21% decrease in FEV₁/FVC with 5 µg/m³ increment in PM_{2.5} with an annual decrease of 0.09%.²⁸ Interestingly, the UK Biobank Study found PM_{2.5}, but not PM₁₀, increment to be associated with FEV₁/FVC decrease,²⁹ while another study from the UK failed to show significant associations between FEV₁/FVC decline and PM₁₀ exposure.³⁶

In contrast to most previous research,^{27–29 34 35 37} we did not find PM_{2.5} or PM₁₀ to be associated with decrements in FVC. This disparity might be related to distinct demography of our study population as well as differences in sources and chemical composition of PM.

The present results also indicated direct correlations between lower-income households (≤¥15 000) and decreased FEV₁ for all three pollutants. This finding illustrates the enhanced effects of air pollution on low-income populations, which can be justified by higher exposure to common health risk factors, substandard living conditions, poorer nutrition, more frequent childhood infections and worse access to healthcare services.³⁸ Similar associations were previously displayed by other studies.^{26 29} In our analysis, PM₁₀ and NO₂ exposure were linked to lower FEV₁ values in elderly individuals, which was also demonstrated previously.³⁶ This might be a valuable complement to the list of other effect modification characteristics. For instance, some studies reported that the history of smoking, obesity or gender was associated with poorer outcomes,^{28 34 36} whereas healthy diet consisting of regular intake of fruits and vegetables mitigated the adverse effects from ambient air pollution.³⁶

The discrepancies in the publications mentioned above may arise from several possible explanations. First, studies varied in the populations assessed and the geographic regions studied. The adjustment for potential confounders was not consistent in all studies, and it is not entirely clear to what extent it could have influenced the outcomes. Second, the exposure assessment of the pollutants differed among cohorts, which might have also impacted the results. Third, in some publications, the heterogeneities between included studies and subgroups could have significantly contributed to the statistical insignificance. Fourth, differences in applied statistical methods (with their respective limitations) might also have played a role in variation in the outcome assessment. Fifth, additive effects of co-pollutants, which is highly likely to vary across world regions, could have influenced the magnitude of the associations within the various endpoints. Last, and possibly most importantly, almost no study assessed different phenotypes of COPD, which can be a critical factor for data stratification.

COPD versus non-COPD

The negative impact of increased exposure to air pollutants on the respiratory function was more pronounced in participants with COPD compared with those without the disease. One of the primary explanations for this finding is the fact that individuals with COPD have already decreased pulmonary physiological function.³⁹ This

group has a higher risk of developing other respiratory diseases, including airway infections and lung cancer, than the general population.²¹ Moreover, individuals with COPD often have other chronic comorbidities, such as cardiovascular disease, as well as mental or metabolic disorders.⁴⁰ Studies showed that patients with COPD have elevated levels of specific inflammatory markers at the

baseline,³¹ which may play an essential role in the mechanisms and progression of the disease.⁴¹

To our knowledge, this is the first study to report the detrimental effects of long-term ambient air pollution on individuals with COPD in comparison to people without COPD. Previous research reported enhanced adverse effects from air pollutants on lung function in

individuals with pre-existing chronic conditions, such as heart disease, asthma, diabetes, obesity or smoking.^{29 36}

Additionally, exposure to air pollution was demonstrated to increase the frequency of COPD exacerbations⁴² and mortality.⁸ An interesting finding was reported by Dorion *et al*, where subjects with occupations considered at risk for COPD (eg, coal mine operatives, chemical and

related process operatives) had three times lower levels of FEV₁ and FVC per each unit increase in PM_{2.5} and NO₂ compared with those with other occupations.²⁹ Forbes *et al* reported the effect modification for PM₁₀, NO₂ and SO₂ when excluding patients with asthma, emphysema or bronchitis compared with the general cohorts.³⁶ However, no direct comparison between these groups was available.

Strengths and limitations

This study has several limitations. First, analyses are limited by the cross-sectional study design and offer little information on the longitudinal effects of evaluated pollutants. Second, differential physical activity patterns, changes in participant addresses and discriminatory infiltration of outdoor pollution to the indoor environment may have contributed to misclassification of exposure levels. Other potential confounding factors, including secondhand tobacco smoking, various environmental components and the impact of other air pollutants, were not assessed. Finally, further studies are warranted to investigate the effects of particulates of different sizes as well as other gaseous pollutants. These limitations are offset by some important strengths. The results of the current study are based on representative populations of adults from eight different provinces in China, whereas most previously published work has been focused on specific areas of the country. Additionally, we were able to adjust for many important confounders and estimated exposure using high-quality spatiotemporal air pollution exposure models.

Future research and conclusions

Although the link between outdoor air pollution and impaired respiratory function has been previously explored, discrepancies in the findings related to the type of pollutants and specific lung function parameters remain. Moreover, there is still a lack of data coming from low-income and middle-income countries. The populations of these countries are of particular interest as they are more often affected by both severe outdoor air pollution and chronic lung diseases, including COPD. The elderly population in Asian countries, including China, is one of the most vulnerable groups in this regard. Air pollution and COPD will continue to be major public health problems worldwide. Considering the ever-ageing global population, future research should focus on older participants with robust study design and powerful statistical models. The influence of COPD phenotype should also be investigated in future studies.

In conclusion, this study contributes to the current evidence regarding the association between ambient air pollution and decreased lung function, as well as increased prevalence of COPD, among adults from developing countries. Our findings further indicate that individuals with COPD are more vulnerable to high levels of

air pollutants with a higher risk of decline in respiratory function.
