Changes in central venous to arterial carbon dioxide gap (PCO₂ gap) in response to acute changes in ventilation

Lisha Shastri, Benedict Kjaergaard, Stephen Edward Rees, Lars Pilegaard Thomsen

ABSTRACT

Background Early diagnosis of shock is a predetermining factor for a good prognosis in intensive care. An elevated central venous to arterial PCO₂ difference (∆PCO₂) over 0.8 kPa (6 mm Hg) is indicative of low blood flow states. Disturbances around the time of blood sampling could result in inaccurate calculations of ∆PCO₂, thereby misrepresenting the patient status. This study aimed to determine the influences of acute changes in ventilation on ∆PCO₂ and understand its clinical implications.

Methods To investigate the isolated effects of changes in ventilation on ∆PCO₂, eight pigs were studied in a prospective observational cohort. Arterial and central venous catheters were inserted following anaesthetisation. Baseline ventilator settings were titrated to achieve an EtCO₂ of 5±0.5 kPa (Vₕ = 8 mL/kg, Freq = 14 ± 2/min). Blood was sampled simultaneously from both catheters at baseline and 30, 60, 90, 120, 180 and 240 s after a change in ventilation. Pigs were subjected to both hyperventilation and hypopojtentilation, wherein the respiratory frequency was doubled or halved from baseline. ∆PCO₂ changes from baseline were analysed using repeated measures ANOVA with post-hoc analysis using Bonferroni’s correction.

Results ∆PCO₂ at baseline for all pigs was 0.76±0.29 kPa (5.7±2.2 mm Hg). Following hyperventilation, there was a rapid increase in the ∆PCO₂, increasing maximally to 1.35±0.29 kPa (10.1±2.2 mm Hg). A corresponding decrease in the ∆PCO₂ was seen following hypopojtentilation, decreasing maximally to 0.23±0.31 kPa (1.7±2.3 mm Hg). These changes were statistically significant from baseline 30s after the change in ventilation.

Conclusion Disturbances around the time of blood sampling can rapidly affect the PCO₂, leading to inaccurate calculations of the ∆PCO₂, resulting in misinterpretation of patient status. Care should be taken when interpreting blood gases, if there is doubt as to the presence of acute and transient changes in ventilation.

INTRODUCTION

For patients in the intensive care unit (ICU), measurements of blood gases are used for the assessment of acid–base and oxygenation status. Many of these patients suffer from sepsis, estimated to affect over 30 million people each year and contributing significantly to the number of hospital deaths. One of the main factors predetermining the prognosis of a patient with sepsis is the presence of septic shock. In the last decade, much research in this area has been focused on the early detection of shock. An elevated CO₂ gap, measured by the difference in central venous (‘cv’) and arterial (‘a’) PCO₂ (∆PCO₂) has been used as an early indicator of shock. Furthermore, the ratio of ∆PCO₂ to the arterial-venous difference in oxygen content (∆PCO₂(cv-a)/∆O₂(a-cv)) has been used to guide and assess the response of fluid resuscitation strategies.

Previous studies have illustrated that significant changes in ∆PCO₂ can be due to circulatory factors, focussing on how venous blood could be modified due to, for example, reduced tissue perfusion and the CO₂ stagnation phenomenon. However, there are other situations that could alter the blood gas parameters in an ICU setting, including spontaneous breathing and/or adjustment of ventilator settings. Disturbances around the time of blood sampling could result in inaccurate calculations of ∆PCO₂ and other relevant parameters. The isolated effects of a disturbance in ventilation on the CO₂ gap have however, not been investigated.

In this study, we hypothesise that acute changes in ventilation affects arterial blood faster than central venous blood and that this may result in clinically significant changes in the CO₂ gap.
in the ∆PCO₂. The aim of this study was, therefore, to determine and quantify the influences of acute changes in ventilation on the ∆PCO₂, concluding on the clinical significance of these changes when interpreting values of ∆PCO₂.

METHODS

This study was designed to investigate changes in ventilation on ∆PCO₂ without the concurrent effects of modification of this gap due to altered tissue perfusion, inclusive of microcirculatory functional shunting. As such, it was decided to study animals (pigs) without cardiovascular or respiratory disease, thus reflecting a more normal physiology. This study was conducted from June 2019 to April 2020 in the Biomedicine Laboratory at Aalborg University Hospital North, Aalborg, Denmark. Eight female Danish Landrace pigs were used for the study. The methods were in line with the Utstein recommendations for uniformity in animal studies.13

Protocol

All pigs were anaesthetised for the duration of the study. The anaesthesia was performed according to local protocols, with total intravenous anaesthesia for the duration of the study, and the presence of indwelling arterial and central venous catheters for blood sampling. The location of the catheters was checked by measurement of the respective blood pressures. Each pig was subjected to both hyperventilation and hypoventilation, with the order of the change in ventilation being randomised.

1. Blood sampling

Simultaneous blood sample pairs were taken by two trained individuals from the arterial and central venous catheters for blood sampling. The location of the catheters was checked by measurement of the respective blood pressures. Each pig was subjected to both hyperventilation and hypoventilation, with the order of the change in ventilation being randomised.

2. Ventilator settings

Mechanically ventilated patients are often on assist mode of ventilation, with spontaneous breathing.14 For these patients, a sudden increase or decrease in respiratory rate is not uncommon,15 the former if the patient becomes stressed and the latter if ventilator support levels are increased and respiratory drive suppressed.16 This study was designed to reflect similar sudden changes in ventilation by varying respiratory frequency. Ventilator settings at baseline and for hyperventilation and hypoventilation are detailed in Table 1. Baseline ventilator settings were titrated to achieve a baseline end tidal CO₂ (EtCO₂) of 5±0.5 kPa. The changes in ventilation corresponded to modifications of respiratory frequency to a high level (28 breaths/min), or a low level (7 breaths/min) which corresponded to an increase of 100% and a decrease of 50% in alveolar ventilation (a dead space of 150 mL was assumed for calculations). The first ventilatory change lasted for 4 min after which it was reverted to baseline for at least 30 min before the pig was subjected to a second change in ventilation. EtCO₂ and SpO₂ were measured throughout the study.

RESULTS

The eight pigs weighed an average of 34.0±8.7 kg, and had mean values of pH and PCO₂ at baseline of 7.478±0.050 and 6.10±0.70 kPa (40.1±4.6 mm Hg) for arterial blood, and 7.440±0.048 and 5.34±0.61 kPa for central venous blood, respectively.

Patient and public involvement

It was not appropriate or possible to involve patients or the public in the design, or conduct, or reporting, or dissemination plans of our research.

Statistical analysis

Eight pigs were studied with each one being subjected to both hyperventilation and hypoventilation. The data from the two changes in ventilation are presented as a change from baseline for pH and PCO₂. ∆PCO₂ was calculated using the difference between PCO₂cv and PCO₂a. Normality of data was tested using Shapiro Wilk’s test and data were found to be normally distributed. Statistical comparisons of the timed arterial blood samples were compared using a repeated measures analysis of variance (ANOVA) followed by a post-hoc analysis comparing the average at each time point to the average at baseline using Bonferroni’s correction. Similar analyses were conducted for central venous blood and ∆PCO₂ following hyperventilation and hypoventilation changes. All results are presented as mean±SD, with p<0.05 considered statistically significant. Statistical analysis was conducted on SPSS V.25 (SPSS IBM Corp.).

Open access

Responses to hyperventilation and hypoventilation
Changes in pH and PCO₂ from baseline at each sampling time are depicted in figure 1 for both arterial and central venous blood. Following acute hyperventilation (figure 1A, B), values of arterial pH and PCO₂ changed faster than venous and were significantly different from baseline at 60 s (p<0.005). The maximum arterial difference was observed at 120 s with pH=0.059 and PCO₂=−0.74 kPa (5.5 mm Hg). There was no statistically significant response observed in the central venous blood over the 4 min.

Following acute hypoventilation (figure 1C, D), there was a similar response in the arterial blood as with hyperventilation, with a rapid and statistically significant difference in values of pH and PCO₂ seen 60 s after the change in ventilation (p<0.005). Central venous blood was significantly different from baseline at 120 s for PCO₂ (p<0.05), while there appeared to be a statistically significant response in pH at 240 s (p = 0.035). Oxygenation did not change for the duration of the study, where the pigs also had a stable and constant FiO₂ and SpO₂.

Effects on ∆PCO₂
Figure 2 illustrates the average changes in ∆PCO₂ following acute changes in ventilation. The average ∆PCO₂ at baseline was 0.76±0.29 kPa (5.7±2.2 mm Hg). Following acute hyperventilation, there was a rapid increase in the ∆PCO₂, with a maximal change of 1.35±0.29 kPa (10.1±2.2 mm Hg). There was a corresponding decrease in the ∆PCO₂ following an acute hypoventilation, decreasing maximally to 0.23±0.31 kPa (1.7±2.3 mm Hg). Changes in ∆PCO₂ in response to both changes in ventilation achieved statistical significance 30 s following an acute change in ventilation (p<0.05).

DISCUSSION
The insertion of a central venous and arterial catheter is common practice for patient management in the intensive care setting, be it for monitoring, fluid and drug administration or blood sampling. Circulatory status of the patient can be assessed by calculation of various parameters using central venous and arterial blood gases, commonly ∆PCO₂. However, especially on assisted ventilation, acute changes in respiratory frequency and/or tidal volume can influence blood acid–base parameters. Previous studies have assessed the effects of circulatory changes on ∆PCO₂. This study is the first to assess the isolated effects of changes in ventilation on ∆PCO₂. The study has demonstrated that ∆PCO₂ responds rapidly to acute changes in ventilation, with these changes due to the influences of ventilation on arterial blood, which are observed without delay, in comparison to central venous blood.

This study shows that acute changes in ventilation can result in ∆PCO₂ changes of ±0.6 kPa. Normal values of ∆PCO₂ have previously been shown to be 0.8 kPa, with patients considered to have insufficient perfusion of the tissues if ∆PCO₂ is above this value. Values of ∆PCO₂ have shown to be elevated to the range of 1.6 to 2 kPa (12–15 mm Hg) for patients with septic shock. The PCO₂ gap has been used in the intensive care departments as a surrogate to identify the onset of anaerobic metabolism, a measure of microcirculatory perfusion and to gauge fluid responsiveness during resuscitation for patients in shock. A measurement of ∆PCO₂ concomitant with hypoventilation or hyperventilation.
resulting in $\Delta PCO_2$ changes of $\pm 0.6\text{kPa}$ is therefore clinically significant, and may result in misclassification of patient state. A clinical example for this could be in the event of hyperventilation in response to metabolic acidosis secondary to tissue hypoxia$^{21}$ in patients with intact respiratory drive, which could acutely affect the $\Delta PCO_2$, causing even higher values than the low flow state of tissue hypoxia itself, leading to misinterpretation of patient prognosis.$^3$ The interpretation of this parameter becomes particularly tricky when narrow cut-off values of $\Delta PCO_2$ or similar indices, for example, the $\Delta PCO_2/\Delta O_2$ ratio, are used. The $\Delta PCO_2/\Delta O_2$ ratio has been shown to be a good marker for global anaerobic metabolism and fluid responsiveness.$^8,^{10}$ A high $\Delta PCO_2/\Delta O_2$ ratio, with cut-offs of $\geq 1.8, \geq 1.6$ or $\geq 0.68 \text{mm Hg/mL}$ have been associated with a worse prognosis.$^6,^{8−10}$ Although the routine use of this ratio in critical care is controversial,$^{22}$ the narrow difference in the cut-offs make it imperative to understand the various influences on blood gas parameters, to be applied during clinical interpretation.

In interpreting these results, it is important to understand the degree to which transient changes in ventilation are seen in these patients, and of what magnitude. Around 80% of sepsis patients admitted into an ICU require ventilatory support, primarily due to the development of acute lung injury and acute respiratory distress syndrome.$^2^5$ For these patients, an initial short period of deep sedation, muscle paralysis and full ventilator control, typically less than 48 hours, is usually followed by the onset of assisted ventilation to preserve respiratory muscle function.$^{14}$ Spontaneous breathing with too little support or asynchrony often results in rapid shallow breathing with high respiratory frequency, similar to that applied in this study.$^{15}$ In contrast, over assistance from the mechanical ventilator has been shown to supress drive and reduce respiratory frequency, with over assistance associated with values of respiratory frequency lower than 12 breaths/min.$^{16}$ It is therefore possible that the rapid changes in $\Delta PCO_2$ of $\pm 0.6\text{kPa}$ shown here are present in the usual treatment of critically ill patients.

**Limitations**

Due to the differences in measurement of oxygen saturation in this animal model, it was not possible to measure oxygenation and therefore calculate changes in $\Delta PCO_2/\Delta O_2$. As inspired oxygenation levels were not changed in this study, and oxygenation is relatively insensitive to ventilation volume, it is likely that $\Delta O_2$ was constant, and that these results apply similarly to that ratio.

**CONCLUSION**

This study has shown that important clinical variation in $\Delta PCO_2$ can be due to acute changes in ventilation, which may result in patient misclassification. Care should be taken when measuring $\Delta PCO_2$ to ensure that ventilation is stable, particularly in patients ventilated with assist modes of ventilation.
